

Electrolysis of Molten Compounds

- A compound is heated until it \_\_\_\_\_ and an \_\_\_\_\_ is passed through it.
- For the circuit to be complete \_\_\_\_\_ must **flow**.
- The \_\_\_\_\_ electrode (anode) attracts \_\_\_\_\_ ions (anions) and takes electrons away from them.
- These flow through the external circuit to the \_\_\_\_\_ electrode.
- The \_\_\_\_\_ electrode (cathode) gives electrons to the \_\_\_\_\_ ions (cations) that it has attracted.
- As ions gain or lose electrons they become \_\_\_\_\_ or \_\_\_\_\_ and are **discharged** from the solution.

**Metal ions** are always \_\_\_\_\_

e.g.  $H^+$   $Li^+$   $Na^+$   $K^+$   $Rb^+$  what do the last 4 have in common?

$Pb^{2+}$   $Fe^{2+}$   $Mg^{2+}$   $Ca^{2+}$   $Str^{2+}$  what do the last 3 have in common?

**Non-metal ions** (except hydrogen,  $H^+$ ) are \_\_\_\_\_

e.g.  $F^-$   $Cl^-$   $Br^-$   $I^-$  what do these 4 ions have in common?

$O^{2-}$   $S^{2-}$

## Electrolysing Molten Compounds

### What type of compounds electrolyse?

- Electrolysis is the \_\_\_\_\_ of a liquid by the passing an electric current through it.
- This can only happen if the compound decomposes to produce \_\_\_\_\_ (charged particles) i.e. ionic compounds made from a metal and \_\_\_\_\_ part.
- The ions are then attracted to the \_\_\_\_\_ (positive electrode) and the \_\_\_\_\_ (negative electrode).
- Ionic compounds are usually solids. Electrolysis will **ONLY** take place when ionic compounds are molten because the ions must \_\_\_\_\_ to the electrodes.

### Example 1 – Consider Sodium Chloride:

### Cathode:

Metal ions \_\_\_\_\_ electrons to become metal atoms

### Anode:

Non-metal ions \_\_\_\_\_ electrons to become atoms or molecules.

We call this type of equation a \_\_\_\_\_.

Predict the

decomposition of the following molten electrolytes:

<u>Electrolyte</u>	<u>positive ions (cations)</u>	<u>negative ions (anions)</u>
sodium chloride $\text{NaCl}$	sodium	chloride
$\text{Al}_2\text{O}_3$		
$\text{PbBr}_2$		
$\text{PbI}_2$		
$\text{KCl}$		

### Half equations:

#### Cathode

#### Anode

## Electrolysis of Aqueous Solutions

What difference does dissolving a compound in water make?

Consider a sodium chloride solution  
(salty water)

- Sometimes the ions from water are more attracted to the electrodes than the ions from the solute (dissolved compound)
- In the solution above, the \_\_\_\_\_ ions are attracted to the anode (+), \_\_\_\_\_ electrons and become \_\_\_\_\_
- The \_\_\_\_\_ ions from water are attracted to the cathode (-) and form \_\_\_\_\_ molecules,  $H_2$ .

Cathode:

\_\_\_\_\_ →

Anode:

\_\_\_\_\_ →

Example 2 Potassium sulfate,  $K_2SO_{4(aq)}$

Cathode:

\_\_\_\_\_ →

Anode:

\_\_\_\_\_ →

Example 3  $KNO_{3(aq)}$

Cathode:

\_\_\_\_\_ →

Anode:

\_\_\_\_\_ →

### Summary

The following 3 solutions all produce hydrogen and oxygen when electrolysed:

$NaCl_{(aq)}$ sodium chloride	} oxygen + hydrogen
$K_2SO_{4(aq)}$ potassium sulfate	
$KNO_{3(aq)}$ potassium nitrate	

## Purifying Copper using Electrolysis

Summary:

Describe the changes in mass of the copper electrodes

- The cathode (negative electrode) \_\_\_\_\_  
mass
- The positive electrode (anode) \_\_\_\_\_  
mass
- The gain in mass of the negative electrode is \_\_\_\_\_ the loss in mass of the positive electrode.

Positive electrode (anode):

Negative electrode (cathode):

What factors affect the amount of copper produced during electrolysis?

- The amount of product made depends on the number of \_\_\_\_\_ transferred
- So the \_\_\_\_\_ the current the more electrons there are. Also, the \_\_\_\_\_ the time the greater the number of electrons transferred.  
more time and higher current = \_\_\_\_\_ mass of pure copper

The relationship between charge transfer, current and time:

$$Q = I t$$

$$Q =$$

$$I =$$

$$t =$$

Units

C (coulombs)

A (amps)

s (seconds)

Example 1

0.96g of copper is deposited by a 0.5A current running for 100 minutes

a) What is the total charge used up?

b) How much charge would be used in 200 minutes?

c) How much charge would be used if we increased the current to 1.0A for 100mins?

Example 2

0.48g of copper is deposited by a 0.25A current running for 100 minutes

a) How much copper is deposited by 1 coulomb of charge?

(hint: work out the total charge first and then divide the mass by the total number of coulombs)

b) If a current of  $0.25\text{A}$  ran for 5 hours how much copper would be deposited?

**A couple of harder challenges** (you won't get these in a GCSE exam!)

c) If a current of  $0.25\text{A}$  is used, how long would be needed to deposit  $9.6\text{g}$  of copper? Give your answer in **hours and minutes** (not just minutes)

*Example 3*

A current of  $5\text{A}$  was used for 60 minutes to produce  $19.5\text{g}$  of lead from molten lead bromide.

a) which electrode will produce the lead?

b) give the chemical formula of the substance produced at the other electrode.

c) Calculate the total charge used in the electrolysis

d) Calculate how much lead  $1\text{ coulomb}$  of charge could produce

f) What mass of lead would be produced if a current of  $30\text{ amps}$  was used for 10 minutes?

e) Suggest two different ways that you could exactly double the amount of lead being produced? (see if you can prove it mathematically)
